

Graphs

In this first part of the book we develop some of the basic ideas behind graph theory – the study of network structure. This approach allows us to formulate basic network properties in a unifying language. The central definitions discussed here are simple enough that we can describe them relatively quickly at the outset; after this, we consider some fundamental applications of the definitions.

2.1 Basic Definitions

Graphs: Nodes and Edges. A *graph* is a way of specifying relationships among a collection of items. A graph consists of a set of objects, called *nodes*, with certain pairs of these objects connected by links called *edges*. For example, the graph in Figure 2.1(a) consists of four nodes labeled A, B, C, and D; node B is connected to each of the other three nodes by edges, and nodes C and D are also connected by an edge. We say that two nodes are *neighbors* if they are connected by an edge. Figure 2.1 shows the typical way to draw a graph: a small circle represents each node, and a line connects each pair of nodes that are linked by an edge.

When looking at Figure 2.1(a), think of the relationship between the two ends of an edge as being symmetric; the edge simply connects them to each other. In many settings, however, we want to express asymmetric relationships – for example, that *A points to B* but not vice versa. For this purpose, we define a *directed graph* to consist of a set of nodes, as before, together with a set of *directed edges*; each directed edge is a link from one node to another, and the direction is important. Directed graphs are generally drawn as in Figure 2.1(b), with edges represented by arrows. When we want to emphasize that a graph is not directed, we can refer to it as an *undirected graph*, but in general the graphs we discuss will be undirected unless noted otherwise.

Graphs as Models of Networks. Graphs are useful because they serve as mathematical models of network structures. With this in mind, it is useful before going further to replace the toy examples in Figure 2.1 with a real example. Figure 2.2 depicts the

Figure 2.1. Two graphs: (a) an undirected graph on four nodes and (b) a directed graph on four nodes.

network structure of the Internet – originally called the Advanced Research Projects Agency Network (ARPANET) – from December 1970 [214], when it had only thirteen sites. Nodes represent computing hosts, and an edge joins two nodes in this drawing if there is a direct communication link between them. Ignoring the superimposed map of the United States (and the circles indicating blown-up regions in Massachusetts and Southern California), we can see that the rest of the image is simply a depiction of this thirteen-node graph using the same dots-and-lines style from Figure 2.1. Note that to show the pattern of connections, the actual placement or layout of the nodes is immaterial; all that matters is which nodes are linked to which other nodes. Thus, Figure 2.3 shows a different drawing of the same thirteen-node ARPANET graph.

Graphs play a role whenever it is useful to represent how things are either physically or logically linked to one another in a network structure. The thirteen-node

Figure 2.3. An alternate drawing of the thirteen-node Internet graph from December 1970.

ARPANET in Figures 2.2 and 2.3 is an example of a *communication network*, in which nodes are computers or other devices that can relay messages and the edges represent direct links along which messages can be transmitted. In Chapter 1, we saw examples from two other broad classes of graph structures: *social networks*, in which nodes are people or groups of people, and edges represent some kind of social interaction; and *information networks*, in which the nodes are information resources such as Web pages or documents, and edges represent logical connections such as hyperlinks, citations, or cross references. The list of areas in which graphs play a role is of course much broader than what can be enumerated here; Figure 2.4 gives a few more examples, and also shows that many images we encounter on a regular basis have graphs embedded in them.

2.2 Paths and Connectivity

We now turn to some of the fundamental concepts and definitions surrounding graphs. An enormous range of graph-theoretic notions have been studied, perhaps because graphs are so simple to define and work with. Indeed, the social scientist John Barnes once described graph theory as a “terminological jungle, in which any newcomer may plant a tree” [45]. Fortunately, for our purposes, we can get under way with just a brief discussion of some of the most central concepts.

Paths. Although we’ve been discussing examples of graphs in many different areas, there are clearly some common themes in the use of graphs across these areas. Perhaps foremost among these is the idea that things often travel across the edges of a graph, moving from node to node in sequence: for example, a passenger taking a sequence of airline flights, a piece of information being passed from person to person in a social network, or a computer user or a piece of software visiting a sequence of Web pages by following links.

This idea motivates the definition of a *path* in a graph: a path is simply a sequence of nodes with the property that each consecutive pair in the sequence is connected by an edge. Sometimes it is also useful to think of the path as containing not just the nodes but also the sequence of edges linking these nodes. For example, the sequence of nodes MIT, BBN, RAND, UCLA is a path in the Internet graph from Figures 2.2 and 2.3, as is the sequence CASE, LINCOLN, MIT, UTAH, SRI, UCSB. As we have defined it here, a path

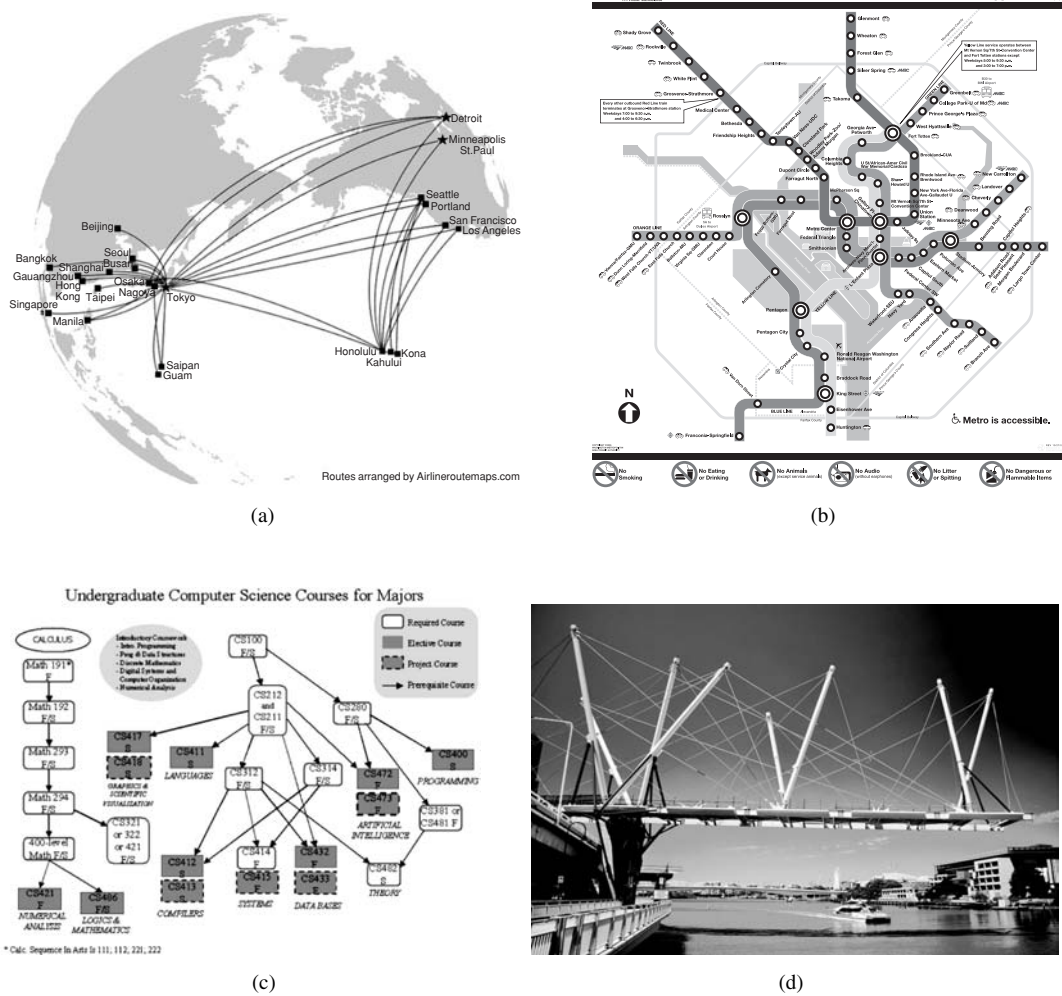

Figure 2.4. Images of graphs arising in different domains. The depictions of (a) airline and (b) subway systems are examples of *transportation networks*, in which nodes are destinations and edges represent direct connections. Much of the terminology surrounding graphs derives from metaphors based on transportation through a network of roads, rail lines, or airline flights. The prerequisites among college courses in part (c) is an example of a *dependency network*, in which nodes are tasks and directed edges indicate that one task must be performed before another. The design of complex software systems and industrial processes often requires the analysis of enormous dependency networks, with important consequences for efficient scheduling in those settings. The bridge in part (d) is an example of a *structural network*, which has joints as nodes and physical linkages as edges. The internal frameworks of mechanical structures such as buildings, vehicles, or human bodies are based on such networks, and the area of *rigidity theory*, which is at the intersection of geometry and mechanical engineering, studies the stability of such structures from a graph-based perspective [388]. (Image sources: (a) www.airlineroutemaps.com/USA/Northwest_Airlines.asia.pacific.shtml, (b) www.wmata.com/metro/systemmap.cfm, (c) www.cs.cornell.edu/ugrad/flowchart.htm, (d) The State of Queensland – Department of Public Works 2009.)

can repeat nodes: for example, SRI, STAN, UCLA, SRI, UTAH, MIT is a path. But most paths we consider will not do this; if we want to emphasize that the path we are discussing does not repeat nodes, we can refer to it as a *simple path*.

Cycles. A particularly important kind of nonsimple path is a *cycle*, which informally is a “ring” structure such as the sequence of nodes LINC, CASE, CARN, HARV, BBN, MIT, LINC on the right-hand side of Figure 2.3. More precisely, a cycle is a path with at least three edges, in which the first and last nodes are the same, but otherwise all nodes are distinct. There are many cycles in Figure 2.3: SRI, STAN, UCLA, SRI is as short an example as possible according to our definition (because it has exactly three edges), while SRI, STAN, UCLA, RAND, BBN, MIT, UTAH, SRI is a significantly longer example.

In fact, every edge in the 1970 ARPANET belongs to a cycle, and this was by design: if any edge were to fail (e.g., if a construction crew accidentally cut through the cable), there would still be a way to get from any node to any other node. More generally, cycles in communication and transportation networks are often present to allow for redundancy; they provide for alternative routes that go the “other way” around the cycle. In a social network of friendships, we also often notice cycles in everyday life, even if we don’t refer to them as such. When you discover, for example, that your wife’s cousin’s close friend from high school is in fact someone who works with your brother, this is a cycle – consisting of you, your wife, her cousin, his high school friend, his coworker (i.e., your brother), and finally back to you.

Connectivity. Given a graph, it is natural to ask whether every node can reach every other node by a path. With this in mind, we say that a graph is *connected* if, for every pair of nodes, there is a path between them. For example, the thirteen-node ARPANET graph is connected; and more generally, one expects most communication and transportation networks to be connected – or at least to aspire to be connected – since the goal is to move traffic from one node to another.

However, there is no a priori reason to expect graphs in other settings to be connected. For example, in a social network, one could easily imagine that there might exist two people for which it is not possible to construct a path from one to the other. Figures 2.5 and 2.6 show examples of disconnected graphs. The first is a simple made-up example, while the second is built from the collaboration graph at a biological research center [134]: nodes represent researchers, and there is an edge between two nodes if the researchers appear jointly on a coauthored publication. (Thus, the edges in Figure 2.6 represent a particular formal definition of collaboration – joint authorship of a published paper – and do not attempt to capture the network of more informal interactions that presumably take place at the research center.)

Components. Figures 2.5 and 2.6 make visually apparent a basic fact about disconnected graphs: if a graph is not connected, then it breaks apart naturally into a set of connected “pieces” – groups of nodes with the property that each group is connected when considered as a graph in isolation, and no two groups overlap. The graph in Figure 2.5 consists of three such pieces: one consisting of nodes A and B, one consisting of nodes C, D, and E, and one consisting of the rest of the nodes. The network in

Figure 2.5. A graph with three connected components.

Figure 2.6 also consists of three pieces: one piece of three nodes, one of four nodes, and one that is much larger.

To make this notion precise, we say that a *connected component* of a graph (often shortened to the term *component*) is a subset of the nodes such that (i) every node in the subset has a path to every other and (ii) the subset is not part of some larger set with the property that every node can reach every other. Notice how both conditions (i) and (ii) are necessary to formalize the intuitive meaning we intend: condition (i) says that the component is indeed internally connected, and condition (ii) says that it is really a free-standing “piece” of the graph, not a connected part of a larger piece. (For example, we would not think of the set of nodes F, G, H, and J in Figure 2.5 as forming a component, because this set violates part (ii) of the definition. Although there are

Figure 2.6. The collaboration graph of the biological research center Structural Genomics of Pathogenic Protozoa (SGPP; [134]), which consists of three distinct connected components. This graph was part of a comparative study of the collaboration-pattern graphs of nine research centers supported by the National Institutes of Health’s Protein Structure Initiative; SGPP was an intermediate case between centers whose collaboration graph was connected and centers for which the graph was fragmented into many small components. (Image from BioMed Central.)

paths among all pairs of nodes in the set, this set belongs to the larger set consisting of F–M, in which all pairs are also linked by paths.)

Dividing a graph into its components is of course only a first, global way of describing its structure. Within a given component, there may be a richer internal structure that is important to an interpretation of the network. For example, thinking about the largest component from Figure 2.6, in light of the collaborations that it represents, one notices certain suggestive features of the structure: a prominent node at the center and tightly-knit groups linked to this node but not to each other. One way to formalize the role of the prominent central node is to observe that the largest connected component would break apart into three distinct components if this node were removed. Analyzing a graph in this way – in terms of its densely connected regions and the boundaries between them – is a powerful way of thinking about network structure, and it will be a central topic in Chapter 3.

Giant Components. There is a useful qualitative way of thinking about the connected components of typical large networks, for which it helps to begin with the following thought experiment. Consider the social network of the entire world, with a link between two people if they are friends. Now, of course, this is a graph that we don't actually have explicitly recorded anywhere, but it is one where we can use our general intuitions to answer some basic questions.

First, is this global friendship network connected? Presumably not. After all, connectivity is a fairly brittle property in that the behavior of a single node (or a small set of nodes) can negate it. For example, a single person with no living friends would constitute a one-node component in the global friendship network, and hence the graph would not be connected. Or the canonical “remote tropical island,” consisting of people who have had no contact with the outside world, would also be a small component in the network, again showing that it is not connected.

But there is something more going on here. If you're a typical reader of this book, then you have friends who grew up in other countries. You're in the same component as all of these friends, since you have a path (containing a single edge) to each of them. Now, if you consider, say, the parents of these friends, your friends' parents' friends, their friends and descendants, then all of these people are in the same component as well – and by now, we're talking about people who have never heard of you, may well not share a language with you, may have never traveled anywhere near where you live, and may have had enormously different life experiences. So even though the global friendship network may not be connected, the component you inhabit seems very large indeed – it reaches into most parts of the world, includes people from many different backgrounds, and seems in fact likely to contain a significant fraction of the world's population.

This is in fact true when one looks across a range of network data sets. Large, complex networks often have what is called a *giant component*, which is a deliberately informal term for a connected component that contains a significant fraction of all nodes. Moreover, when a network contains a giant component, it almost always contains only one. To see why, let's go back to the example of the global friendship network and try to imagine that there were two giant components, each with hundreds of millions of people. All it would take is a single edge from someone in the first of these components

Figure 2.7. A network in which the nodes are students in a large American high school, and an edge joins any two who had a romantic relationship at some point during the 18-month period in which the study was conducted [49]. (Image from The University of Chicago Press.)

to someone in the second, and the two giant components would merge into a single component. In most cases, it's essentially inconceivable that some such edge wouldn't form, and hence two coexisting giant components are something one almost never sees in real networks. When a giant component exists, it is thus generally unique and distinguishable as a component that dwarfs all others.

In fact, in some of the rare cases when two giant components have coexisted for a long time in a real network, their merging has been sudden, dramatic, and ultimately catastrophic. For example, Jared Diamond's book *Guns, Germs, and Steel* [130] devotes much of its attention to the cataclysm that befell the civilizations of the Western Hemisphere when European explorers began arriving in it roughly half a millennium ago. One can view this development from a network perspective as follows: 5,000 years ago, the global social network likely contained two giant components – one in the Americas and one in the Europe–Asia land mass. Because of this division, technology evolved independently in the two components and, perhaps even worse, human diseases also evolved independently; when the two components finally came in contact, the technology and diseases of one quickly and disastrously overwhelmed the other.

The notion of giant components is also useful for reasoning about networks on much smaller scales. The collaboration network in Figure 2.6 is one simple example; another interesting example is depicted in Figure 2.7, which shows the romantic relationships in an American high school over an 18-month period [49]. (These edges were not all present at once; rather, there is an edge between two people if they were romantically involved at any point during the time period.) The fact that this graph contains such a

large component is significant when one thinks about the spread of sexually transmitted diseases, which was a focus of the researchers performing the study. A high school student may have had a single partner over this time period and nevertheless – without realizing it – may have been part of this large component and hence part of many paths of potential transmission. As Bearman, Moody, and Stovel note in their analysis of this network, “These structures reflect relationships that may be long over, and they link individuals together in chains far too long to be the subject of even the most intense gossip and scrutiny. Nevertheless, they are real: like social facts, they are invisible yet consequential macrostructures that arise as the product of individual agency.”

2.3 Distance and Breadth-First Search

In addition to simply asking whether two nodes are connected by a path, it is also interesting in most settings to ask how *long* such a path is; in transportation, Internet communication, or the spread of news and diseases, it is often important whether something flowing through a network has to travel just a few hops or many.

To be able to talk about this notion precisely, we define the *length* of a path to be the number of steps it contains from beginning to end – in other words, the number of edges in the sequence that comprises it. Thus, for example, the path MIT, BBN, RAND, UCLA in Figure 2.3 has length 3, while the path MIT, UTAH has length 1. Using the notion of a path’s length, we can talk about whether two nodes are close together or far apart in a graph. In particular, the *distance* between two nodes in a graph is defined as the length of the shortest path between them. For example, the distance between the nodes LINC and SRI is 3, although to believe this you have to first convince yourself that there is no length 1 or length 2 path between them.

Breadth-First Search. For a graph like the one in Figure 2.3, we can generally figure out the distance between two nodes just by looking at the picture, but for graphs that are even somewhat more complicated, we need some systematic method to determine distances.

The most natural way to do this – and also the most efficient way to calculate distances for a large network data set using a computer – is the way you would probably do it if you really needed to trace out distances in the global friendship network (and had the unlimited patience and cooperation of everyone in the world). This procedure is pictured in Figure 2.8.

1. First declare all of your actual friends to be at a distance of 1.
 2. Then find all of *their friends* (not counting people who are already friends of yours), and declare these to be at a distance of 2.
 3. Then find all of *their friends* (again, not counting people whom you’ve already found at distances of 1 and 2) and declare these to be at a distance of 3.
- (...) Continuing in this way, search in successive layers, each of which represents the next distance out. Each new layer is built from all those nodes that (i) have not already been discovered in earlier layers and (ii) have an edge to some node in the previous layer.

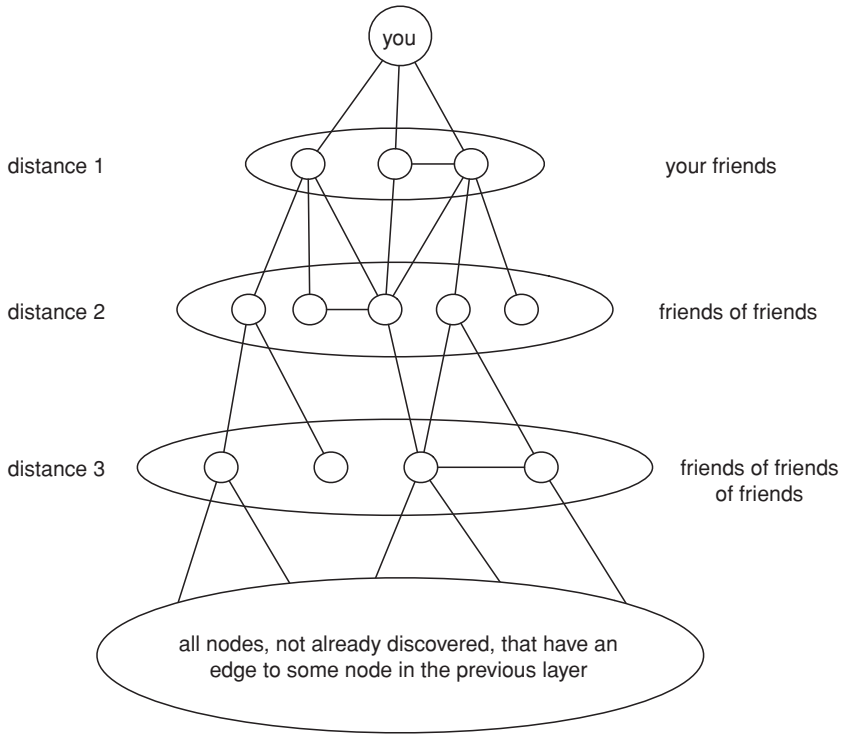

Figure 2.8. Breadth-first search discovers the distances to nodes one “layer” at a time; each layer is built of nodes that have an edge to at least one node in the previous layer.

This technique is called *breadth-first search*, since it searches the graph outward from a starting node, reaching the closest nodes first. In addition to providing a method of determining distances, it can also serve as a useful conceptual framework to organize the structure of a graph, arranging the nodes based on their distances from a fixed starting point.

Of course, despite the social-network metaphor we used to describe breadth-first search, the process can be applied to any graph: one just keeps discovering nodes in a layer-by-layer fashion, building each new layer from the nodes that are connected to at least one node in the previous layer. For example, Figure 2.9 shows how to discover all distances from the node MIT in the thirteen-node ARPANET graph from Figure 2.3.

The Small-World Phenomenon. As with our discussion of the connected components in a graph, there is something qualitative we can say, beyond the formal definitions, about distances in typical large networks. If we go back to our thought experiments on the global friendship network, we see that the argument explaining why you belong to a giant component in fact asserts something stronger: not only are there paths of friends connecting you to a large fraction of the world’s population, but these paths are surprisingly *short*. Take the example of a friend who grew up in another country: following a path through this friend, to his or her parents, and to their friends, you have followed only three steps and ended up in a different part of the world, in a different generation, with people who have very little in common with you.

Figure 2.9. The layers arising from a breadth-first of the December 1970 ARPANET, starting at the node MIT.

This idea has been termed the *small-world phenomenon* – the idea that the world looks “small” when you think of how short a path of friends it takes to get from you to almost anyone else. It is also known, perhaps more memorably, as the *six degrees of separation*; this phrase comes from the play of this title by John Guare [200], and in particular from the line uttered by one of the play’s characters: “I read somewhere that everybody on this planet is separated by only six other people. Six degrees of separation. Between us and everyone else on this planet.”

The first experimental study of this notion – and the origin of the number “six” in the pop-cultural mantra – was performed by Stanley Milgram and his colleagues in the 1960s [297, 391]. Lacking any of the massive social-network data sets available today, and with a budget of only \$680, Milgram set out to test the speculative idea that people are really connected in the global friendship network by short chains of friends. To this end, he asked a collection of 296 randomly chosen “starters” to try forwarding a letter to a “target” person – a stockbroker who lived in a suburb of Boston. The starters were each given some personal information about the target (including his address and occupation) and were asked to forward the letter to someone they knew on a first-name basis, with the same instructions, to eventually reach the target as quickly as possible. Each letter thus passed through the hands of a sequence of friends in succession, and each thereby formed a chain of people that closed in on the stockbroker outside Boston.

Figure 2.10 shows the distribution of path lengths among the sixty-four chains that succeeded in reaching the target; the median length was six – the number that made its way two decades later into the title of Guare’s play. That so many letters reached their destination, and by such short paths, was a striking fact when it was first discovered, and it remains so today. Of course, it is worth noting a few caveats about the experiment. First, the experiment clearly does not establish a statement quite as bold as “six degrees of separation between us and everyone else on this planet”: the paths were just to a

Figure 2.10. A histogram from Travers and Milgram’s paper on their small-world experiment [391]. For each possible length (labeled “number of intermediaries” on the x-axis), the plot shows the number of successfully completed chains of that length. In total, sixty-four chains reached the target person, with a median chain length of six. (Image from the American Sociological Association.)

single, fairly affluent target; many letters never arrived; and attempts to re-create the experiment have been problematic due to lack of participation [255]. Second, one can ask how useful these short paths really are to people in society: even if you can reach someone through a short chain of friends, is this fact useful to you? Does it mean you’re truly socially “close” to them? Milgram himself mused about this in his original paper [297]; his observation, paraphrased slightly, was that if we think of each person as the center of their own social “world,” then “six short steps” becomes “six worlds apart” – a change in perspective that makes six sound like a much larger number.

Despite these caveats, the experiment and the phenomenon that it hints at have formed a crucial aspect in our understanding of social networks. In the years since the initial experiment, the overall conclusion has been accepted in a broad sense: social networks tend to have very short paths between essentially arbitrary pairs of people. And even if your six-step connections to chief executive officers and political leaders don’t yield immediate payoffs on an everyday basis, the existence of all of these short paths has substantial consequences for the potential speed with which information, diseases, and other kinds of contagion can spread through society, as well as for the potential access that the social network provides to opportunities and to people with very different characteristics. All these issues, and their implications for the processes that take place in social networks, are rich enough that we will devote Chapter 20 to a more detailed study of the small-world phenomenon and its consequences.

Figure 2.11. The distribution of distances in the graph of all active Microsoft Instant Messenger user accounts, in which an edge joins two users if they communicated at least once during a month-long observation period [273].

Instant Messaging, Paul Erdős, and Kevin Bacon. One reason for the current empirical consensus that social networks generally are “small worlds” is that this notion has been increasingly confirmed in settings where we do have full data available on the network structure. Milgram was forced to resort to an experiment in which letters served as “tracers” through a global friendship network that he had no hope of fully mapping on his own; but for other kinds of social network data in which the full graph structure is known, one can just load it into a computer and perform a breadth-first search procedure to determine what typical distances look like.

One of the largest such computational studies was performed by Jure Leskovec and Eric Horvitz [273]. They analyzed the 240 million active user accounts on Microsoft Instant Messenger (IM) and built a graph in which each node corresponds to a user. There is an edge between two users if they engaged in a two-way conversation at any point during a month-long observation period. As employees of Microsoft at the time, Leskovec and Horvitz had access to a complete snapshot of the system for the month under study, so there were no concerns about missing data. This graph turned out to have a giant component containing almost all of the nodes, and the distances within this giant component were very small. Indeed, the distances in the IM network closely corresponded to the numbers from Milgram’s experiment, with an estimated average distance of 6.6 and an estimated median of 7. Figure 2.11 shows the distribution of distances averaged over a random sample of 1,000 users: breadth-first search was performed separately from each of these 1,000 users, and the results from these 1,000 nodes were combined to produce the plot in the figure. The reason for this estimation by sampling users is computational: the graph was so large that performing

graph, with paths leading to Paul Erdős [189]. Now, a mathematician's *Erdős number* is the distance from him or her to Erdős in this graph [198]. The point is that most mathematicians have Erdős numbers of at most 4 or 5, and – extending the collaboration graph to include coauthorship across all the sciences – most scientists in other fields have Erdős numbers that are comparable or only slightly larger: Albert Einstein's is 2; Enrico Fermi's is 3; Noam Chomsky's and Linus Pauling's are each 4; and Francis Crick's and James Watson's are 5 and 6, respectively. The world of science is truly a small one in this sense.

Inspired by some mixture of the Milgram experiment, John Guare's play, and a compelling belief that Kevin Bacon was the center of the Hollywood universe, three students at Albright College in Pennsylvania sometime around 1994 adapted the idea of Erdős numbers to the collaboration graph of movie actors and actresses: nodes are performers, an edge connects two performers if they've appeared together in a movie, and a performer's *Bacon number* is his or her distance in this graph to Kevin Bacon [372]. Using cast lists from the Internet Movie Database (IMDb), it is possible to compute Bacon numbers for all performers via breadth-first search; and as with mathematics, it's a small world indeed. The average Bacon number, for all performers in the IMDb, is approximately 2.9, and it is a challenge to find one that's larger than 5. Indeed, it's fitting to conclude with a movie enthusiast's description of his late-night attempts to find the largest Bacon number in the IMDb by hand: "With my life-long passion for movies, I couldn't resist spending many hours probing the dark recesses of film history until, at about 10 AM on Sunday, I found an incredibly obscure 1928 Soviet pirate film, *Plenniki Morya*, starring P. Savin with a Bacon number of 7, and whose supporting cast of 8 appeared nowhere else" [197]. One is left with the image of a long exploration that arrives finally at the outer edge of the movie world – in the early history of film, in the Soviet Union – and yet in another sense, only eight steps from where it started.

2.4 Network Data Sets: An Overview

The explosion of research on large-scale networks in recent years has been fueled to a significant extent by the increasing availability of large, detailed network data sets. We've seen examples of such data sets throughout these first two chapters, and it is useful at this point to step back and think more systematically about where people have been getting the data that they employ in large-scale studies of networks.

To put this in perspective, we note first of all that there are several distinct reasons why you might study a particular network data set. One reason is that you may care about the actual domain that the data set comes from, so that fine-grained details of the data are potentially as interesting as the broad picture. Another reason is that you may be using the data set as a proxy for a related network that is impossible to measure – for example, in the way the Microsoft IM graph from Figure 2.11 gave us information about distances in a social network of a scale and character that begins to approximate the global friendship network. A third possibility is that you may be looking for network properties that appear to be common across many different domains, and so finding

a similar effect in unrelated settings can suggest that it has a certain universal nature, with possible explanations that are not tied to the specifics of any one of the domains.

Of course, all three of these motivations are often at work simultaneously, to varying degrees, in the same piece of research. For example, the analysis of the Microsoft IM graph gave us insight into the global friendship network. However, at a more specific level, the researchers performing the study were also interested in the dynamics of instant messaging in particular, and at a more general level, the results of the IM graph analysis fit into the broader framework of small-world phenomena that span many domains.

As a final point, here we are concerned with sources of data on networks that are *large*. If one wants to study a social network on 20 people – say, within a small company, or a fraternity or sorority, or a karate club as in Figure 1.1 – then one strategy is to interview all the people involved and to ask them who their friends are. But if we want to study the interactions among 20,000 people, or 20,000 individual nodes of some other kind, then we need to be more opportunistic in where we look for data: except in unusual cases, we can't simply go out and collect everything by hand, and so we need to think about settings in which the relevant information has in some essential way already been collected for us.

With this in mind, let's consider some of the main sources of large-scale network data that people have used for research. The resulting list is far from exhaustive, and the categories are not truly distinct – a single data set can easily exhibit characteristics from several.

Collaboration Graphs. Collaboration graphs record who works with whom in a specific setting; coauthorships among scientists and coappearance in movies by actors and actresses are two examples of collaboration graphs that we discussed in Section 2.3. Another example that has been extensively studied by sociologists is the graph of highly placed people in the corporate world, with an edge joining two if they have served together on the board of directors of the same Fortune 500 company [301]. The online world provides new instances: the Wikipedia collaboration graph (connecting two Wikipedia editors if they've ever edited the same article) [122, 246] and the World of Warcraft (WoW) collaboration graph (connecting two WoW users if they've ever taken part together in the same raid or other activity) [419] are just two examples.

Sometimes a collaboration graph is studied to learn about the specific domain it comes from; for example, sociologists who study the business world have a substantive interest in the relationships among companies at the director level, as expressed via comembership on boards. On the other hand, while there is a research community that studies the sociological context of scientific research, a broader community of people is interested in scientific coauthorship networks precisely because they form detailed, predigested snapshots of a rich form of social interaction that unfolds over a long period of time [318]. By using online bibliographic records, one can often track the patterns of collaboration within a field across a century or more, and thereby attempt to extrapolate how the social structure of collaboration may work across a range of harder-to-measure settings as well.

Who-Talks-to-Whom Graphs. The Microsoft IM graph is a snapshot of a large community engaged in several billion conversations over the course of a month. In this way, it captures the “who-talks-to-whom” structure of the community. Similar data sets have been constructed from the e-mail logs within a company [6] or a university [259], and also from records of phone calls: researchers have studied the structure of *call graphs* in which each node is a phone number, and there is an edge between two phone numbers if they were engaged in a phone call over a given observation period [1, 334]. One can also use the fact that mobile phones with short-range wireless technology can detect other similar devices nearby. By equipping a group of experimental subjects with such devices and studying the traces they record, researchers can thereby build “face-to-face” graphs that represent physical proximity: a node in such a graph is a person carrying one of the mobile devices, and an edge joins two people if they were detected to be in close physical proximity over a given observation period [141, 142].

In almost all of these kinds of data sets, the nodes represent customers, employees, or students of the organization that maintains the data. These individuals generally have strong expectations of privacy, not necessarily even appreciating how easily one can reconstruct details of their behavior from the digital traces they leave behind when communicating by e-mail, instant messaging, or phone. As a result, the style of research performed on this kind of data is generally restricted in specific ways that protect the privacy of the individuals involved. Such privacy considerations have also become a topic of significant discussion in settings in which companies try to use this type of data for marketing, or when governments try to use it for intelligence-gathering purposes [315].

Related to this kind of who-talks-to-whom data, economic network measurements recording the “who-transacts-with-whom” structure of a market or financial community have been used to study the ways in which different levels of access to market participants can lead to different levels of market power and different prices for goods. This empirical work has in turn motivated more mathematical investigations of how a network structure limiting access between buyers and sellers can affect outcomes [63, 176, 232, 261], which will be a focus of our discussion in Chapters 10–12.

Information Linkage Graphs. Snapshots of the Web are central examples of network data sets; nodes are Web pages and directed edges represent links from one page to another. Web data stands out both in its scale and in the diversity of what the nodes represent: billions of little pieces of information with links wiring them together. And clearly it is not just the information that is of interest, but the social and economic structures that stand behind the information: hundreds of millions of personal pages on social-networking and blogging sites, and hundreds of millions more representing companies and governmental organizations trying to engineer their external images in a crowded network.

A network on the scale of the full Web can be daunting to work with; simply manipulating the data effectively can become a research challenge in itself. As a result, much network research has been done on interesting, well-defined subsets of the Web, including the linkages among bloggers [264], among pages on Wikipedia [404],

among pages on social-networking sites such as Facebook or MySpace [185], and among discussions and product reviews on shopping sites [201].

The study of information linkage graphs significantly predates the Web: the field of *citation analysis* has, since the early part of the twentieth century, studied the network structure of citations among scientific papers or patents, as a way of tracking the evolution of science [145]. Citation networks are still popular research data sets today for the same reason that scientific coauthorship graphs are: even if you don't have a substantive interest in the social processes by which science gets done, citation networks are very clean data sets that can easily span many decades.

Technological Networks. Although the Web is built on a lot of sophisticated technology, it would be a mistake to think of it primarily as a technological network: it is really a projection onto a technological backdrop of ideas, information, and social and economic structure created by humans. But as we noted in the opening chapter, there has been a convergence of social and technological networks in recent years, and many interesting network data sets come from the more overtly technological end of the spectrum, in which nodes represent physical devices and edges represent physical connections between them. Examples include the interconnections among computers on the Internet [155] or among generating stations in a power grid [411].

Even physical networks like these are ultimately economic networks as well, representing the interactions among the competing organizations, companies, regulatory bodies, and other economic entities that shape them. On the Internet, this relationship is made particularly explicit by a two-level view of the network. At the lowest level, nodes are individual routers and computers, and an edge indicates that two devices actually have a physical connection to each other. But, at a higher level, these nodes are grouped into what are essentially little “nation-states” termed *autonomous systems*, each one controlled by a different Internet service provider. There is then a who-transacts-with-whom graph on the autonomous systems, known as the *AS graph*, that represents the data-transfer agreements these Internet service providers make with each other.

Networks in the Natural World. Graph structures also abound in biology and the other natural sciences, and network research has devoted particular attention to several different types of biological networks. The following are three examples at three different scales, from the population level down to the molecular level.

1. As a first example, *food webs* represent the who-eats-whom relationships among species in an ecosystem [137]: there is a node for each species, and a directed edge from node A to node B indicates that members of A consume members of B. Understanding the structure of a food web as a graph can help in reasoning about issues such as *cascading extinctions*: if certain species become extinct, then species that rely on them for food also risk becoming extinct if they do not have alternative food sources; these extinctions can propagate through the food web as a chain reaction.
2. Another heavily studied network in biology is the structure of neural connections within an organism's brain: the nodes are neurons, and an edge represents a

connection between two neurons [380]. The global brain architecture for simple organisms like *C. elegans*, with 302 nodes and roughly 7,000 edges, has essentially been completely mapped [3], but obtaining a detailed network picture for brains of higher organisms is far beyond the current state of the art. However, significant insight has been gained by studying the structure of specific modules within a complex brain and understanding how they relate to one another.

3. A final example is the set of networks that make up a cell's metabolism. There are many ways to define these networks, but roughly, the nodes are compounds that play a role in a metabolic process, and the edges represent chemical interactions among them [43]. Researchers hope that analysis of these networks can shed light on the complex reaction pathways and regulatory feedback loops that take place inside a cell, and perhaps suggest “network-centric” attacks on pathogens that disrupt their metabolism in targeted ways.

2.5 Exercises

1. One reason for graph theory's power as a modeling tool is the fluidity with which one can use it to formalize the properties of large systems using the language of graphs, and then to systematically explore their consequences. In this first set of questions, we work through an example of this process using the concept of a *pivotal* node.

Recall from earlier in the chapter that a *shortest path* between two nodes is a path of the minimum possible length. We say that a node X is *pivotal* for a pair of distinct nodes Y and Z if X lies on every shortest path between Y and Z (and X is not equal to either Y or Z).

For example, in the graph in Figure 2.13, node B is pivotal for two pairs: the pair consisting of A and C , and the pair consisting of A and D . [Notice that B is not pivotal for the pair consisting of D and E because two different shortest paths connect D and E , one of which (using C and F) does not pass through B . Therefore, B is not on every shortest path between D and E .] As another example, note that node D is not pivotal for any pairs.

- (a) Give an example of a graph in which every node is pivotal for at least one pair of nodes. Explain your answer.
- (b) Give an example of a graph in which every node is pivotal for at least two different pairs of nodes. Explain your answer.

Figure 2.13. In this example, node B is pivotal for two pairs: the pair consisting of A and C , and the pair consisting of A and D ; node D is not pivotal for any pairs.

Figure 2.14. Node A is a gatekeeper; node D is a local gatekeeper but not a gatekeeper.

- (c) Give an example of a graph having at least four nodes in which there exists a single node X that is pivotal for every pair of nodes (not counting pairs that include X). Explain your answer.
2. In the next set of questions, we consider a related cluster of definitions that seek to formalize the idea that certain nodes can play a “gatekeeping” role in a network. The first definition is the following. We say that a node X is a *gatekeeper* if, for some other two nodes Y and Z , every path from Y to Z passes through X . For example, in the graph in Figure 2.14, node A is a gatekeeper, because it lies on every path from B to E. (It also lies on every path between other pairs of nodes – for example, the pair D and E, as well as other pairs.)

This definition has a certain “global” flavor, because it requires that we think about paths in the full graph to decide whether a particular node is a gatekeeper. A more “local” version of this definition could involve only looking at the neighbors of a node. The following is a way to make this definition precise: we say that a node X is a *local gatekeeper* if there are two neighbors of X , say Y and Z , that are not connected by an edge. (That is, for X to be a local gatekeeper, there should be two nodes Y and Z such that Y and Z each have edges to X , but not to each other.) For example, in Figure 2.14, on the one hand, node A is a local gatekeeper in addition to being a gatekeeper; node D, on the other hand, is a local gatekeeper but not a gatekeeper. (Node D has neighbors B and C, which are not connected by an edge; however, every pair of nodes – including B and C – can be connected by a path that does not go through D.)

So we have two new definitions: *gatekeeper* and *local gatekeeper*. When faced with new mathematical definitions, a strategy that is often useful is to explore them first through examples and then to assess them at a more general level and try to relate them to other ideas and definitions. Let’s try this in the next two questions.

- (a) Give an example (together with an explanation) of a graph in which more than half of all nodes are gatekeepers.
- (b) Give an example (together with an explanation) of a graph in which there are no gatekeepers but in which every node is a local gatekeeper.
3. When we think about a single aggregate measure to summarize the distances between the nodes in a given graph, two natural quantities come to mind. One is the *diameter*, which we define to be the maximum distance between any pair of nodes in the graph. Another is the *average distance*, which, as the term suggests, is the average distance over all pairs of nodes in the graph.

In many graphs, these two quantities are close to each other in value. But there are graphs where they can be very different.

- (a) Describe an example of a graph where the diameter is more than three times as large as the average distance.
- (b) Describe how you could extend your construction to produce graphs in which the diameter exceeds the average distance by as large a factor as you would like. (That is, for every number c , can you produce a graph in which the diameter is more than c times as large as the average distance?)
